ABSTRACT

The Communications Research Laboratory and the NTT Telecommunication Network Laboratory Group have developed a highly precise very long baseline interferometry (VLBI) system using a high-speed asynchronous transfer mode (ATM) network. The observed data is transmitted through a 2.488-Gbps ATM network [STM-16/OC-48] instead of being recorded onto magnetic tape. In this system, cross-correlation processing and data observation are done simultaneously, one operator can handle both the observation and the processing. It takes about one hour to analyze the data after the observation and correlation completed. In regular geodetic VLBI experiments run every other day for 24 hours, a horizontal position uncertainty of about 1 mm and a vertical position uncertainty of about 10 mm were achieved. This system is a significant advance in VLBI and should provide more precise information about crustal deformation in the Tokyo metropolitan area.

Keywords: Real-time VLBI, ATM, Correlation system

1. Introduction

We developed an even more precise VLBI[1, 2] system for the Key Stone Project[3] (KSP), to measure crustal deformation in the Tokyo metropolitan area. Three of the four stations are unmanned, while the central station (Koganei) is run by one operator who manages the observation and correlation processing. Two systems with a horizontal accuracy of 1 mm are in operation, and 24-hour VLBI experiments are being run every other day. One system is tape-based, and the other is a real-time system. In the tape-based system, the observed data is recorded on magnetic tape at the observing site, and the tapes are sent to the correlation site by mail. The analysis is done the next day, so it takes at least one day to obtain the measured crustal deformation. This delay is eliminated in the real-time system, which uses an ATM[4] network to send the data. The network has a transmission capability of up to 2.488 Gbps through optical-fiber links. The four stations are connected to this ATM network. The data is transmitted from the remote observing stations to the correlation site, where it is processed in real time. The data is processed using the tape-based correlation processor and the analysis software. This real-time system greatly improves VLBI performance.

2. ATM Network

A block diagram of the real-time VLBI system is shown in Fig. 1. The ATM network transmits the information in fixed-length packets called cells. A cell (AAL type 1) is composed of 53 bytes of data in total, a 5-byte header and a 48-byte payload, with 1 byte used as a sequence number to check for cell loss and mis-delivery. The signals input to the ATM transmitter are written

into the payload of the ATM cell in arrival order (Fig. 2). The cell header showing the destination is attached when the payload is filled; the cell is then output to the 2.488-Gbps transmission path [STM-16/OC-48]. The signals from the four stations are transmitted to a cross-connect switch that merges them onto one path. A virtual path identifier (VPI) in the header shows the destination virtual path. It is possible to transmit data at various rates over the same transmission path.

In the receiver (Fig. 3), the multiplexed signal (cells) is disassembled, then reassembled into signals corresponding to each station by using the destination in the cell header data. The system has functions that compensate for the transmission-line delay, absorb cell-delay fluctuations, and compensate for mistaken cell delivery and cell loss in the receiver. The delay suffered by each cell depends on the cross-connect switching timing. Therefore, the cell interval is not preserved in the network, so the arrival interval differs from the initial interval. This cell delay variation depends on the number devices the cells must pass through, the data rate, the transmission-line accommodation rate, and the traffic characteristics in the virtual path. The cell-delay fluctuations are absorbed in the receiver by using a 40-kbit buffer memory (more than 100 cells); the cells are reassembled so that the data is regularly spaced, the spacing is equal to that on the transmitter side.

Cell loss or mis-delivery may occur in the transmission of signals through the ATM network. For VLBI, mistaken delivery and cell loss that lead to bit-make and bit-slip actions are considered as fatal errors. If cell loss occurs, the lost bits are re-inserted using the same number of bits, and if a cell is mistakenly delivered, it is removed.

3. VLBI Data Acquisition System

The KSP data-acquisition system (Fig. 4), a high-end version of the K-4/KSP system[6], has a maximum record-

ing rate of 256 Mbps and is fully automatic. It consists of a reference distributor, an IF distributor, a local oscillator, a video converter, an input interface, a data recorder, and a digital mass storage system (automatic tape changer). The local oscillator synthesizes the local frequency signal for the video converter, which converts the windows in the IF-signal (500-1000 MHz) input into video signals. The frequency conversion is done using an image rejection mixer and single-sideband conversion. The input interface samples the video signal received from the video converter and sends the digital data to the data recorder and/or the ATM transmitter together with the time-data, which is phase locked to an external time reference. The input interface quantizes the 16-channel (max.) video signal and produces a data train of 256 Mbps (max.). The K-4 input interface was designed to make the best possible use of the recording ability (up to 256 Mbps) of the K-4 recorder (which uses the ANSI ID-1

Fig. 7 Photograph of data-acquisition system. Shown from left is the ATM transmitter, the weather-monitoring equipment rack, the antenna-control equipment rack, the receiver-control and monitoring equipment rack, the backend equipment rack, and the digital mass-storage system. Three IF signals are received by IF receivers in the receiver-control and monitoring equipment rack. They are sent to an IF distributor in the backend equipment rack. Two sets of video converters (500 - 1000 MHz: 8 ch/unit) convert the signals to video signals. The video signals are sent to the input interface (black panel), and the digital data is sent to the digital mass-storage system. The data is recorded on magnetic tapes or sent to the ATM transmitter.

observation. The data rate selection; 256, 128, 64, 32, 16 (Mbps), of the ATM was automatically synchronized to input data. After correlation, the data was analyzed using the SOLVE 5.0 and CALC 8.1[8] software developed by the Goddard Space Flight Center. The IERS standard s[9] were used for the model calculation. The Earth rotation parameters (ERP) for the *a priori* calculation were obtained from the IERS forecast data. The signal sources were 16 stars. Over 100 observations were made over five hours. The differences between the results obtained using the real-time and tape-based systems were less than 2 mm along the baseline vector and 2 mm along the baseline length. The correlated amplitude using the tape-based system was coincident with that of the real-time system. There were no effective differences between the results of the two systems.

For four 22-hour real-time VLBI experiments, we obtained a formal error in the baseline length (109099656.11 mm) of 1.78 mm and a station position error (in vector) of less than 1.8 mm. The RMS of the residual delay from the fitting line using daily experimental data was 1.3 mm, which is within the formal error (1.8 mm).

6. Conclusion

A photograph of the data-acquisition system is shown Fig. 7. The photograph in Fig. 8 shows the real-time correlation system. The KSP system uses two data-transfer systems: a tape-based system and a real-time system. Both systems were designed to be fully automatic, so only one operator can handle both the observation and correlation processing. The two systems can be operated simultaneously. Using the tape-based system, we ran 5-hour experiments daily starting in January 1995. The real-time

VLBI system has been used instead of the tape-based system since April 1997. Following a continuous 120-hour 256-Mbps test session (from July 28 to August 1, 1997), a 24-hour experiment has been run every other day starting September 30, 1997. In regular geodetic VLBI experiments run every other day for 24 hours, a horizontal position uncertainty of about 1 mm and a vertical position uncertainty of about 10 mm were achieved. The obtained results are available to the public via the Internet (http://ksp.crl.go.jp).
